Keywords: Stick-slip instability, Extrusion, Compressibility, Slip, Pressure oscillations.

Abstract. The time-dependent, two-dimensional compressible Newtonian flow over the reservoir-die region is solved assuming that slip occurs along the die wall following a non-monotonic slip law. The combination of compressibility and nonlinear slip leads to self-sustained oscillations of the pressure drop and of the mass flow rate at constant piston speed, when the latter falls into the unstable negative slope regime of the flow curve. The effect of the reservoir volume on the amplitude, the frequency and the waveform of the pressure oscillations is studied and comparisons are made with experimental observations concerning the stick-slip polymer extrusion instability.

1 INTRODUCTION

Slip at the wall is considered to be a key factor in polymer extrusion instabilities, such as the stick-slip instability[1,2]. A characteristic of the stick-slip instability not encountered with other types of extrusion instability, such as sharkskin and gross melt fracture, is that this is accompanied by pressure and mass flow rate oscillations which result in extrudate shapes characterized by alternating rough and smooth regions[1,2]. Recent work concerning numerical modeling of the stick-slip instability has been reviewed by Achilleos et al.[3] who discuss three different instability mechanisms: (a) combination of nonlinear slip with compressibility; (b) combination of nonlinear slip with elasticity; and (c) constitutive instabilities. In the present work, we investigate further the compressibility-slip instability by means of numerical simulations.

The compressibility-slip mechanism has been tested by Georgiou and Crochet[4,5] in the Newtonian case, with the use of an arbitrary non-monotonic slip equation relating the wall shear stress to the slip velocity. These authors numerically solved the time-dependent compressible Newtonian Poiseuille and extrudate-swell flows with non-linear slip at the wall, showing that steady-state solutions in the negative-slope regime of the flow curve (i.e. the plot of the wall shear stress versus the apparent shear rate or the plot of the pressure drop versus the volumetric flow rate) are unstable, in agreement with linear stability analysis. Self-sustained oscillations of the pressure drop and of the mass flow rate at the exit are obtained, when an unstable steady-state solution is perturbed, while the volumetric flow rate at the inlet is kept constant. These oscillations are similar to those observed experimentally with the stick-slip extrusion instability. In a recent work, Georgiou[6] obtained similar results for the compressible, axisymmetric Poiseuille and extrudate-swell flows of a Carreau fluid with slip at the wall, using an empirical slip equation that is based on the experimental measurements of Hatzikiriakos and Dealy[7,8] on a HDPE melt. Unlike the experimental observations[8,9,10], however, the limit cycles of the periodic solution obtained in all these numerical studies do not follow the steady-state branches of the flow curve.

As pointed out by Georgiou[6], including the reservoir is necessary in order to account for the compression and decompression of most part of the fluid, and obtain limit cycles following the steady-state branches of the flow curve, i.e. for obtaining pressure and extrudate flow rate oscillations characterized by abrupt changes, as is the experiments. Only such abrupt changes can lead to extrudates with alternating relatively smooth and sharkskin regions, which is the basic characteristic of the stick-slip instability. Note that the reservoir region is taken into account in various one-dimensional phenomenological models, which are also based on the compressibility/slip mechanism[11]. These describe very well the pressure oscillations but they are not predictive, because they require as input certain experimental parameters.

The objective of the present work is to extend the simulations of Georgiou[6] by including the reservoir
region and study the effect of the reservoir length on the pressure oscillations. According to experiments\cite{8,9,12}, the period of the oscillations scales roughly with the volume of the polymer melt in the reservoir. Weill\cite{9} and Durand et al.\cite{10} also studied experimentally the effect of the reservoir length on the durations of compression and relaxation and found that both times increase linearly with the reservoir length, which indicates that the latter does not affect the waveform of the oscillations.

In Section 2, the governing equations, the slip equation and the boundary and initial conditions are discussed. In Section 3, we describe briefly the numerical method, present the numerical results, and make comparisons with experimental observations. Finally, in Section 4, we summarize the conclusions.

2 GOVERNING EQUATIONS AND BOUNDARY CONDITIONS

The geometry of the flow corresponds to the actual setup used in the experiments of Hatzikiriakos and Dealy\cite{8}. There is a contraction region at 45 degrees between the barrel and the die as shown in Fig. 1. The actual values of the radii of the barrel and the die, denoted respectively by \( R_b \) and \( R \), and the length of the die, \( L \), are tabulated in Table 1. In the simulations, the length of the barrel, \( L_b \), varied from 20\( R \) to 200\( R \).

To non-dimensionalize the governing equations, we scale the lengths by the capillary radius, \( R \), the velocity vector, \( v \), by the mean velocity \( V \) in the capillary, the pressure, \( p \), by \( \eta V / R \), \( \eta \) denoting the constant viscosity, the density, \( \rho \), by a reference density, \( \rho_0 \), and the time by \( R / V \). With these scalings, the dimensionless continuity and momentum equations for time-dependent, compressible, isothermal viscous flow in the absence of body forces become:

\[
\frac{\partial \rho}{\partial t} + \nabla \cdot \rho \mathbf{v} = 0
\]  

(1)
and

\[ \text{Re} \rho \left( \frac{\partial \mathbf{v}}{\partial t} + \mathbf{v} \cdot \nabla \mathbf{v} \right) = -\nabla p + \nabla^2 \mathbf{v} \]  \hspace{1cm} (2)

where \( \text{Re} \) is the Reynolds number, defined by

\[ \text{Re} = \frac{\rho_0 RV}{\eta} \]  \hspace{1cm} (3)

The above equations are completed by an equation of state relating the pressure to the density. We used the first-order expansion:

\[ \rho = 1 + B \rho \]  \hspace{1cm} (4)

where \( B \) is the compressibility number,

\[ B = \frac{\beta \eta V}{R} \]  \hspace{1cm} (5)

\( \beta \) being the isothermal compressibility.

Along the capillary wall, slip is assumed to occur following the three-branch multi-valued slip model:

\[ v_w = \begin{cases} A_1 \sigma_{w,1}' \sigma_{w,2}', & 0 \leq v_w \leq v_{c,2} \\ A_2 \sigma_{w,2}' \sigma_{w,3}', & v_{c,2} \leq v_w \leq v_{\text{min}} \\ A_3 \sigma_{w,3}' \sigma_{w,3}', & v_w \geq v_{\text{min}} \end{cases} \]  \hspace{1cm} (6)

where \( v_w \) is the relative dimensionless velocity of the fluid with respect to the wall, \( \sigma_{w,1}' \) is the dimensionless shear stress on the wall, \( v_{c,2} \) is the maximum slip velocity at \( \sigma_{c,2} \), and \( v_{\text{min}} \) is the minimum slip velocity at \( \sigma_{\text{min}} \). The third branch is the power-law slip equation suggested by Hatzikiriakos and Dely [8] for the right branch of their flow curve. The first branch results from the slip equation they propose for the left branch of their slope curve after substituting all parameters for resin A at 180°C and taking the normal stress as infinite. Finally, the second negative-slope branch, which corresponds to the unstable region of the flow curve for which no measurements have been possible, is just the line connecting the other two branches. The values of all the slip equation parameters and the definitions of the dimensionless numbers \( A_i \) can be found in Ref. 6.

The other boundary conditions of the flow are shown in Fig. 1. Along the axis of symmetry, we have the usual symmetry conditions. Along the barrel and the contraction walls both velocity components are zero (no slip). Along the capillary wall, only the radial velocity is zero, whereas the axial velocity satisfies the slip equation (6). At the inlet plane, it is assumed that the radial velocity component is zero while the axial velocity is uniform, corresponding to the motion of the piston at constant speed. Note that the imposed volumetric flow rate, \( Q \), is scaled by \( \pi R^2 V \). The simulations are carried out on a fixed domain, i.e. the motion of the piston is not taken into account. This is a reasonable assumption provided that the piston speed is low. At the capillary exit, the radial velocity component and the total normal stress are assumed to be zero.

Finally, as initial condition, we use the steady-state solution corresponding to a given volumetric flow rate \( Q_{\text{old}} \) that we perturb to \( Q \) at \( t=0 \).

3 NUMERICAL RESULTS

We use the finite element formulation for solving this Newtonian flow problem, employing biquadratic-velocity and bilinear-pressure elements. For the spatial discretization of the problem, we use the Galerkin forms of the continuity and momentum equations. For the time discretization, the standard fully-implicit (Euler backward-difference) scheme is used. Various finite element meshes have been used in the simulations with the reservoir length, \( L_b \), ranging from 20 to 200. These were refined near the walls, and around the entrance of the capillary. The longest mesh (\( L_b=200 \)) consisted of 4511 elements corresponding to 42403 unknowns. In all results presented below the following values for the slip equation parameters and the compressibility number
have been used: \( m_1 = 3.23 \), \( A_1 = 0.0583 \), \( m_2 = 2.86 \), \( A_2 = 0.929 \), \( m_3 = 4.43 \), \( A_3 = 4.04 \), and \( B = 1.54 \times 10^{-4} \).

We first constructed the steady-state flow curves for the reservoir-capillary region. In Fig. 2, we show the log-log plot of the pressure drop, measured along the centerline from the piston to the die exit, versus the volumetric flow rate obtained with \( Re = 0.01 \) and \( L_b = 80 \). Due the non-monotonicity of the slip equation, the flow curve exhibits a maximum and a minimum, which define the limits of the unstable regime, i.e. only the steady-state solutions corresponding to the two positive-slope branches are stable. As already mentioned, the steady-state solutions are perturbed by changing the volumetric flow rate from an old value to the desired one \( Q \). Given that the flow is compressible, the behavior of the time-dependent solution depends on whether the new value of \( Q \) corresponds to a positive-slope branch, or to the negative-slope branch which is unstable. In the first case, the new steady-state is obtained without any oscillations, whereas, in the second case, the solution is oscillatory and, after a transition period, becomes periodic. Self-sustained oscillations of the pressure drop and the mass flow rate are obtained which are similar to those observed experimentally in the stick-slip extrusion instability regime. All the results presented below have been obtained in the unstable regime.

![Figure 2. Flow curve for \( Re = 0.01 \) and \( L_b = 80 \)](image)

In Fig. 3, we show the oscillations of the pressure drop (Fig. 3a) and the volumetric flow rate (Fig. 3b) obtained by perturbing the steady-state solution for \( Re = 0.01 \), \( L_b = 80 \) and \( Q = 1.35 \). In Fig. 3a, we show two different possibilities when the pressure drop is measured across the entire flow domain, \( (\Delta P)_{tot} \), and across the capillary, \( (\Delta P)_{cap} \). Sudden jumps of the pressure drop are observed in the latter case. The volumetric flow rate at the capillary exit is also characterized by sudden jumps which is consistent with experimental observations. Plotting the trajectory of the solution on the flow curve plane (Fig. 4) shows that, after a transition period, a limit cycle is reached which follows exactly the positive-slope branches of the steady-state flow curve. The volumetric flow rate increases together with the pressure following exactly the left positive-slope branch of the flow curve and, when the pressure reaches its maximum value, \( Q \) jumps to the right positive slope branch. The volumetric flow rate then starts decreasing together with the pressure following this branch till the pressure reaches its minimum and then jumps to the left positive-slope branch and starts the next oscillation cycle. This behavior agrees well with experimental observations\cite{8,10}. Note also that in our previous study\cite{6}, the limit cycles did not follow the steady-state flow curve due to the omission of the reservoir region. This drawback was also exhibited by the one-dimensional model of Greenberg and Demay\cite{13}, which does not include the barrel region. Note that one-dimensional phenomenological relaxation/oscillation describe the oscillations of the pressure and the volumetric flow rate in the stick-slip instability regime under the assumption that these follow the experimental flow curve\cite{14,15}. The present simulations are the first to show that the limit cycle follows the steady-state flow curve.
We then reduced the value of the $Re$ from 0.01 to 0.001 in an attempt to approach the experimental value ($1.43 \times 10^{-5}$). As shown in Fig. 5, where we compare the oscillations of $\Delta P$ during one cycle for $Re=0.01$ and 0.001, $L_b=80$ and $Q=1.35$, decreasing the Reynolds number has no practical effect on the oscillations. However, the artificial overshoots are observed in the flow rate. Thus instead of trying to eliminate the overshoots by reducing the time step (which would have resulted into much longer runs), we decided to continue the runs with $Re=0.01$. Note that in our previous study\[^6\] for the extrudate-swell flow, in which the reservoir region has been excluded, we observed that as the Reynolds number is reduced the amplitude of the pressure-drop oscillations is reduced, the amplitude of the mass-flow-rate oscillations is increased and the frequency of the oscillations is considerably increased. This shows once again the importance of including the reservoir region.
Figure 5. Comparison of the pressure oscillations for Re=0.01 and 0.001; $L_b=80$ and $Q=1.35$

Figure 6. Effect of the reservoir length on the pressure oscillations; $Q=1.35$ and $Re=0.01$
In order to study the effect of the reservoir length on the pressure oscillations we obtained results for various values of $L_b$. In Fig. 6, we show the pressure oscillations for different values of $L_b$, $Re=0.01$ and $Q=1.35$. We observe that the period of the pressure oscillations increases with $L_b$ while their amplitude seems to be less sensitive. This is more clearly shown in Fig. 7, where the period and the amplitude of the pressure oscillations are plotted versus the reservoir volume. In agreement with experiments with different polymer melts\cite{6,10,16,17}, the period $T$ increases linearly with the reservoir volume while the amplitude is essentially constant. In Fig. 7a, the period appears to pass through the origin which is not the case with the experiments. Finally, in order to show the effect of the reservoir on the waveform of the pressure oscillations we plotted the normalized pressure oscillations during one cycle for $L_b =20$ and 200 (Fig. 8). The waveform is independent of the reservoir length, i.e., the durations of the compression and relaxation increase linearly with the reservoir length. This agrees well with the experiments of Weill\cite{8}, Hatzikiriakos and Dealy\cite{8} and Durand et al.\cite{10}.

4 CONCLUSIONS

We solved numerically the time-dependent, compressible flow of a Newtonian fluid over the reservoir-capillary region, assuming that slip occurs along the capillary wall following a non-monotonic slip law based on the experimental findings of Hatzikiriakos and Dealy\cite{7,8} for certain polyethylene melts. By using meshes of different length, we have studied the effect of the reservoir length on the pressure oscillations occurring when the imposed flow rate falls in the unstable negative-slope regime of the flow curve. Our calculations showed that the pressure oscillations follow the steady-state flow curve and that their period increases linearly with the reservoir length, while their amplitude and waveform remain unaffected. These results are in good agreement with the experiments of Weill\cite{9}, Hatzikiriakos and Dealy\cite{8}, Durand et al.\cite{10}, and others, which have also shown that the period and the shape of the pressure oscillations vary also with the imposed flow rate, where their amplitude remains unaffected. The effect of $Q$ on the pressure oscillations is currently under study.
